Assessment of *E. regnans* Tree Height at Kaingaroa Cpt. 333

Summary

The third generation *Eucalyptus regnans* progeny trial growing in Kaingaroa forest was assessed for height growth aged 30 months. Tree health and survival was good apart from some wind toppling. Growth was excellent, with an average tree height of 6.2 metres at 30 months. No particular provenance trends were detected. Height growth was variable across the trial in part due to the sheltering effect of an adjacent stand of radiata pine.

Trees growing next to windrows had more space and had a competitive advantage. Attempts were made to remove the differences in height growth due to environmental factors using spatial analysis. A full list of estimated breeding values for each family and the best individual from each family are provided. In a few years time the trees will be assessed for tree form, before the final selections are made to take forward to form the next generation.

Authors: Stuart Kennedy, Charlie Low, Scion

Introduction

The trial was planted from seed collected from selections made in the second generation *E. regnans* trial in Kaingaroa Cpt. 1194, where the trees had been devastated by dieback caused by leaf fungi. The trial is an incomplete block design, 3 incomplete blocks per replicate, 30 replicates of single-tree plots of approximately 90 families and one control seedlot.

Tree height was measured in decimetres using height poles. A list of family means can be found in Appendix 2. Tree growth has been spectacular (Figure 1) with the average height of all trees 6.2 metres, at two and a half years old. The fastest growth was in the most sheltered part of the trial near the large radiata pine on the southwest side, where average height is around 7 metres and some trees around 9 metres. The weeds are also an indicator of site quality and were growing best in this area with the tutu being particularly vigorous and some bracken fern emerging. Diameter growth is around one centimetre per metre of height, so the trees are very slender for their height compared to radiata pine.

Very little browsing by paropsis was seen, although a couple of gum emperor moth cocoons were found. A handful of the smallest

trees had some sort of leader dieback and 'sick' foliage, but trees in poor health were rare. Some leaders were smashed out, presumably by the strong winds experienced in March 2012, and generally occurred where trees had forked. Incidence of forking was low (4.5%), while survival was high (95.6%).

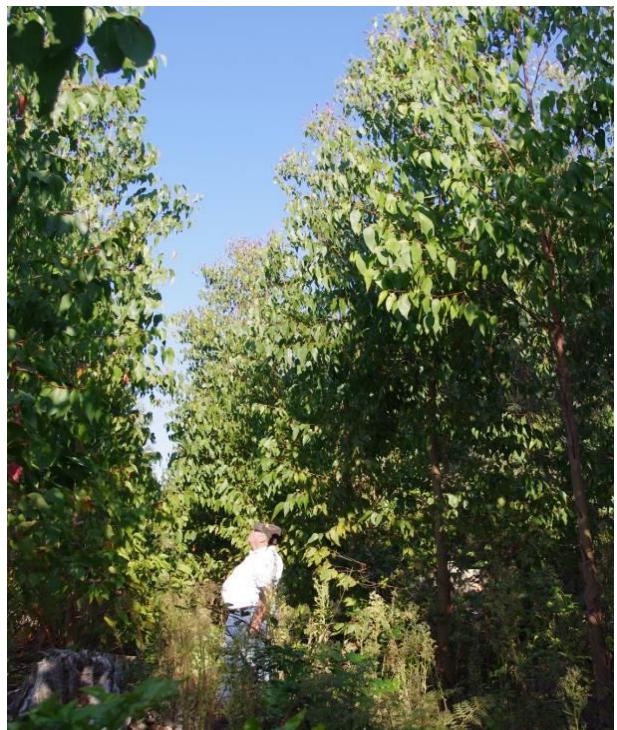

Figure 1: Height growth of *E. regnans* growing in Kaingaroa aged 30 months.

DIVERSIFIED SPECIES TECHNICAL NOTE

Number: DSTN-034

Date: September 2012

There had been some toppling shortly after planting and some trees have substantial buttsweep. The recent strong winds of a month ago have also brought some trees down. Pigs have done some substantial digging, mainly around decaying radiata pine stumps in their search for huhu grubs. The root systems of some trees have been exposed / damaged by pig-rooting.

Analysis

Eucalyptus species can be effected by micro site changes, for this reason (where significant) data was analysed spatially to remove as much of the micro site variation as possible. Genetic parameters and breeding values were estimated (Appendix 3) for traits using mixed model equations (Appendix 1) that were solved using the software package ASReml-R.

Discussion of Results

The best family (code 74) was 6.8 metres tall, while the worst was 4.9 metres. Survival was excellent, with the poorest survival being 25 out of 30 trees planted. No particular provenance trends were apparent, nor was there any indication that the third generation families originally planted at Wiltsdown were doing better than second generation families that were imported from Australia.

There was variable height growth across the trial. A height gradient exists across the trial from right to left (Figure 2). The right-most region of the trial had the tallest trees due to being sheltered by a mature stand of radiata pine. The replicates were set out perpendicular to this environmental gradient so much of the variation in tree height across the trial will be accounted for by replicates. The top and bottom edges of the trial (Figure 2) border forest roads and have seen higher compaction upon removal of the previous radiata pine crop likely accounting for the reduced height growth in these regions of the trial.

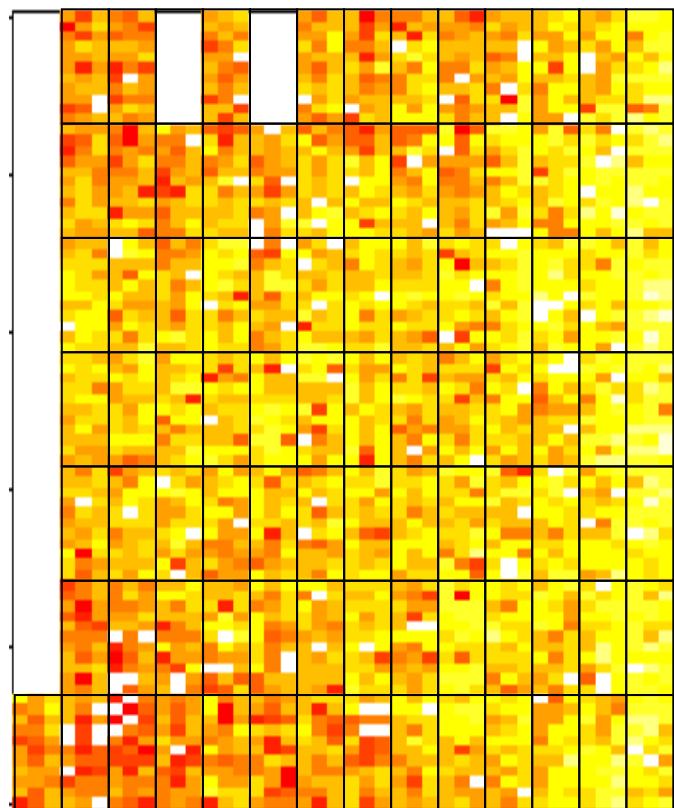

Figure 2: Raw height data, white boxes indicate missing trees, red boxes smallest trees and yellow boxes largest trees. Block boundaries (3 trees by 11) are indicated by the overlain grid.

The more subtle and concerning variation in tree height growth was the apparent difference in tree height between the windrow edges and the middle row of trees growing in each replicate. The two outer rows of each replicate that border a windrow where slash has been gathered appeared to be taller due to the greater growing space compared to the row growing in the middle of each replicate. The worry being that replicate edge trees with their growth advantage may not fully be accounted for by the trial design impacting upon the estimation of breeding values. Spatial analysis was conducted in an attempt to account for this trial layout effect resulting from the original land preparation. The residuals from the spatial analysis (Figure 3A) clearly show a replicate row effect with the middle row of every replicate having a lower residual variance. Row was fitted as a fixed effect in the model (Appendix 1 – Model 4) to try

DIVERSIFIED SPECIES TECHNICAL NOTE

Number: DSTN-034

Date: September 2012

and remove unwanted variation between rows from the analysis (Figure 3B).

A list of parental breeding values for height estimated using model 4 (Appendix 1) are in Appendix 3. Breeding values are an estimate of the genetic merit for each tree for each trait. The trees are large enough to select from based on the current height assessment. Some trees may be producing seed now, but it is likely to be at

least another two years before any large scale collection can be made. Before selecting the final trees for the next generation of the breeding cycle it would be prudent to assess tree straightness and form. The best individual of each parent is also provided (Appendix 3), so that scion material can be collected from the best individual from the better families present in the trial to form a seed orchard.

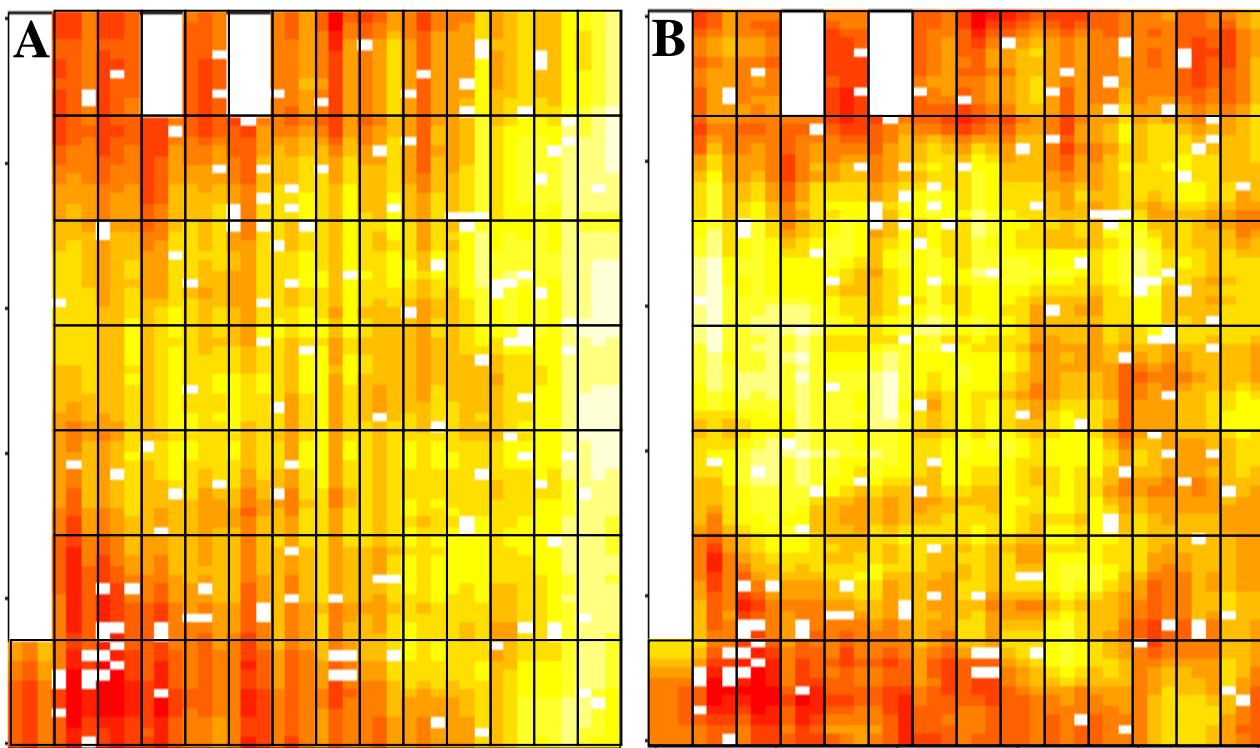

Figure 3: Plotted residuals following spatial analysis (A), displaying the linear residual variation due to the window effect. Row was fitted as a fixed effect (B), removing much of the linear residual variation. White boxes indicate missing trees, red boxes smallest residual and yellow boxes greatest residual. Block boundaries (3 trees by 11) are indicated by the overlain grid.

LogL	-8050.2		-7973.5		-7904.6		-7814.9	

Note. The basic model used was as follows; $y = Xb + Z_1a + Z_2r + Z_3r.b + e$ where y is the vector of individual-tree observations on a trait, b is a vector of fixed effects (i.e., mean (and in the case of the final model used row)), a is a vector of random additive genetic effects of individual genotypes, r is a vector of random replicate effects, $r.b$ is the random interaction between replicate and block, and e is a vector of random residual effects. X , Z_1 , Z_2 and Z_3 are known incidence matrices relating the observations in y to effects in b , a , r and $r.b$ respectively. Row and column were added to the design, placing each tree in a grid enabling trees to be analysed spatially.
